Abstract

We introduce `ctsem` (Driver, Oud, and Voelkle 2015), an R package for continuous time structural equation modelling of panel ($N > 1$) and time series ($N = 1$) data, using either full information maximum likelihood or the Kalman filter. Most dynamic models for longitudinal data in the social and behavioural sciences are discrete time models. An assumption of discrete time models is that time intervals between measurements are equal, and that all subjects were assessed at the same intervals. Violations of this assumption are regularly ignored due to the difficulty of accounting for varying time intervals, therefore parameter estimates can be severely biased. By using stochastic differential equations and estimating an underlying continuous process, continuous time models allow for any pattern of measurement occasions. By interfacing to a general purpose SEM package (`OpenMx`), `ctsem` combines the flexible specification of structural equation models with the enhanced data gathering opportunities and improved estimation of continuous time models. `ctsem` can estimate relationships over time for multiple latent processes, measured by multiple noisy indicators with varying time intervals between observations. Within and between effects are estimated simultaneously by modelling both observed covariates and unobserved heterogeneity. Exogenous shocks with different shapes, group differences, higher order diffusion effects and oscillating processes can all be simply modelled. We first briefly introduce and define continuous time models, then show how to specify and estimate a range of continuous time models using `ctsem`.

Keywords: time series, panel data, state Space, structural equation modelling, continuous time, stochastic differential equation, dynamic models, Kalman filter, R.

1. Introduction

Dynamic models, such as the well known vector autoregressive model, are widely used in the social and behavioural sciences. They allow us to see how fluctuations in processes relate to later values of those processes, the effect of an input at a particular time, how the various factors relate to average levels of the processes, and many other possibilities. Some examples with panel data include the impact of European institutional changes on business cycles (Canova, Ciccarelli, and Ortega 2012), the coupling between sensory and intellectual functioning (Ghisletta and Lindenberger 2005), or the analysis of bidirectional links between

children’s delinquency and the quality of parent-child relationships (Keijsers, Loeber, Branje, and Meeus 2011). Examples of single subject approaches are studies on the decline in pneumonia rates in the USA after a vaccine introduction (Grijalva, Nuorti, Arbogast, Martin, Edwards, and Griffin 2007), or the lack of a relationship between antidepressant sales and public health in Iceland (Helgason, Tǎşmasson, and Zoega 2004). At present, applications of dynamic models in the social and behavioural sciences are almost exclusively limited to *discrete time models*. In discrete time models it is assumed that time progresses in discrete steps, that time intervals between measurement occasions are equal, and that, in case of panel data, all subjects are assessed with the same time intervals. In many cases, these assumptions are not met, resulting in biased parameter estimates. This concept is illustrated in Figure 1. In the upper panel, Figure 1 shows a true autoregressive effect of .80 between observed variables (represented by squares), assuming equal intervals of length $\Delta t = 1$ (represented by equal distances between observed variables), while the lower panel shows a process with two intervals of $\Delta t = 1$ and one interval $\Delta t = 2$. In the top panel, the meaning of the estimate of .80 is clear – it refers to the autoregression estimate for 1 unit of time. In the lower case, however, the autoregression estimate of .73 is ambiguous – it is too low to characterise the relation between the first three occasions (correct value of .80 is in brackets) and too high between the last two occasions (correct value of .64).

Figure 1: Two autoregressive processes, each exhibiting a true autoregressive effect of .80 for 1 unit of time. The top process is measured with equal time intervals (represented by the space between observations) of 1 unit, while the lower process has unequal intervals.

Obviously, parameter estimates and, thus, scientific conclusions, are biased when observation intervals vary and this is not adequately accounted for. In simple cases, such as the example in Figure 1, additional variables – so called phantom variables (Rindskopf 1984), with missing values for all individuals – could be added in order to artificially create equally spaced time intervals. For example, an additional variable could be specified at t_4 , resulting in equal time intervals and permitting the use of standard discrete time models. For complex patterns of individually varying time intervals, however, this approach quickly becomes untenable (Voelkle and Oud 2013). Furthermore, based on discrete time models it is difficult to compare results obtained from different studies with unequal time intervals, which poses a limitation to the production of cumulative knowledge in science (Voelkle, Oud, Davidov, and Schmidt 2012).

Continuous time models overcome these problems, offering researchers the possibility to estimate parameters free from bias due to unequal intervals, easily compare between studies

and datasets with different observation schedules, gather data with variable time intervals between observations, and parsimoniously specify complex dynamics. Although continuous time models have a long history (Coleman 1964; Hannan and Tuma 1979), their use in the social sciences is still uncommon. At least in part, this is due to a lack of suitable software to specify and estimate continuous time models. With the introduction of **ctsem** in this article, we want to overcome this limitation. Although we will define continuous time models in the next section and provide several examples in the sections thereafter, a comprehensive treatment of continuous time models is beyond the scope of this article. For a more general introduction to continuous time models by means of SEM, the reader is referred to Voelkle *et al.* (2012). For additional information on the technical details we refer the reader to Oud and Jansen (2000).

The R package **ctsem** interfaces to **OpenMx** (Boker *et al.* 2011), a powerful general purpose SEM package for R (R Core Team 2014). This allows **ctsem** to capitalize on all the possibilities of structural equation models, including manifest and latent variables, flexibility in imposing parameter constraints, multiple group functionality, as well as the use of different fitting functions and non-linear constraints. Most importantly, by interfacing to **OpenMx** the user may tailor standard continuous time models to his or her specific needs. **OpenMx** was chosen as the basis for **ctsem** because of its capacity to incorporate the necessary matrix algebra constraints, such as the matrix exponential.

The remainder of this article is organised as follows: in Section 2, we provide a formal definition of continuous time models. In Section 3 we will show how to install **ctsem** and give an overview of the package. In Section 4, we will review different data structures and discuss the role of time in continuous time models. In Section 5, we will show how to specify continuous time models in **ctsem**, followed by a discussion of model estimation and testing in Section 6. In Section 7 we will discuss various extensions of basic continuous time models, including unobserved heterogeneity, time dependent and time independent exogenous predictors, time series, multiple group models, additional models of the diffusion process, and the analysis of oscillations. We will end with some discussion of various specification options and tips for model fitting in Section 8, and point to current limitations and future research and development directions in Section 9.

2. Continuous time models: fundamentals

The class of continuous time models implemented in **ctsem** is represented by the multivariate stochastic differential equation:

$$\mathbf{\eta}_i(t) = (\mathbf{A}\mathbf{\eta}_i(t) + \mathbf{B}\mathbf{z}_i + \mathbf{M}\mathbf{x}_i(t) + \boldsymbol{\xi}_i)dt + \mathbf{G}d\mathbf{W}_i(t) \quad (1)$$

Vector $\mathbf{\eta}_i(t) \in \mathbb{R}^{v \times 1}$ is a v -variable vector of the processes of interest at time t , for subject i . The $v \times v$ matrix \mathbf{A} represents the so-called drift matrix, with auto effects on the diagonal and cross effects on the off-diagonals characterising the temporal relationships of the processes.

\mathbf{B} is a $v \times p$ matrix with parameters describing the effect of the vector of time independent predictors $\mathbf{z} \in \mathbb{R}^{p \times 1}$ on $\mathbf{\eta}_i(t)$.

\mathbf{M} is a $v \times l$ matrix with parameters describing the effect of time dependent predictors $\mathbf{x}_i(t) \in \mathbb{R}^{l \times 1}$ on $\mathbf{\eta}_i(t)$.

The base level of the processes is captured by the v -length vector of random variables ξ_i , with $\xi \sim N(\kappa, \phi_\xi)$, where the value κ denotes the continuous time intercepts, and value ϕ_ξ the covariance across subjects. The continuous time intercepts set the long-term level of the processes – without them the processes of a stable model would always trend towards zero in the long-run.

$\mathbf{W}_i(t)$ represents the diffusion process, specifically here the Wiener process, a random-walk in continuous time. This is multiplied by \mathbf{G} which determines the variance and covariance. \mathbf{Q} , where $\mathbf{Q} = \mathbf{G}\mathbf{G}^\top$, represents the variance-covariance matrix of the diffusion process in continuous time.

The solution of the stochastic differential Equation 1 for any time interval $t - t_0$ is:

$$\begin{aligned} \eta_i(t) = & e^{\mathbf{A}(t-t_0)}\eta_i(t_0) + \\ & \mathbf{A}^{-1}[\mathbf{e}^{\mathbf{A}(t-t_0)} - \mathbf{I}]\mathbf{B}\mathbf{z}_i + \\ & \int_{t_0}^t e^{\mathbf{A}(t-s)}\mathbf{M}\mathbf{x}_i(s)ds + \\ & \mathbf{A}^{-1}[\mathbf{e}^{\mathbf{A}(t-t_0)} - \mathbf{I}]\xi_i + \\ & \int_{t_0}^t e^{\mathbf{A}(t-s)}\mathbf{G}d\mathbf{W}_i(s) \end{aligned} \quad (2)$$

The five terms of this equation correspond to the five terms of Equation 1, and give the link between the continuous model and discrete instantiations of the process. The last term, the integral of the diffusion over the given time interval, exhibits covariance matrix:

$$\text{cov}\left[\int_{t_0}^t e^{\mathbf{A}(t-s)}\mathbf{G}d\mathbf{W}_i(s)\right] = \int_{t_0}^t e^{\mathbf{A}(t-s)}\mathbf{Q}e^{\mathbf{A}^\top(t-s)}ds = \text{irow}\left\{\mathbf{A}_\#^{-1}[\mathbf{e}^{\mathbf{A}_\#(t-t_0)} - \mathbf{I}]\text{row}\mathbf{Q}\right\} \quad (3)$$

Where $\mathbf{A}_\# = \mathbf{A} \otimes \mathbf{I} + \mathbf{I} \otimes \mathbf{A}$, with \otimes denoting the Kronecker-product, row is an operation that takes elements of a matrix rowwise and puts them in a column vector, and irow is the inverse of the row operation.

Within **ctsem** time dependent predictors observed at time u are treated as singular impulses on the processes, as such the third term becomes:

$$e^{\mathbf{A}(t-u)}\mathbf{M}\mathbf{x}_i(u) \quad (4)$$

The process vector $\eta_i(t)$ may be directly observed or latent with measurement model

$$\mathbf{Y}_i(t) = \mathbf{\Gamma}_i + \mathbf{\Lambda}\eta_i(t) + \delta_i(t), \quad \text{where } \delta(t) \sim N(\mathbf{0}, \mathbf{\Theta}), \quad \text{and } \mathbf{\Gamma} \sim N(\boldsymbol{\tau}, \boldsymbol{\epsilon}) \quad (5)$$

where c -length vector $\boldsymbol{\tau}$ is the expected value of $\mathbf{\Gamma}_i$, which is distributed across subjects according to $c \times c$ covariance matrix $\boldsymbol{\epsilon}$ (referred to later as *manifest traits* – see Section 7.1). $\mathbf{\Lambda}$ is a $c \times v$ matrix of factor loadings, $\mathbf{Y}_i(t) \in \mathbb{R}^{c \times 1}$ is a c -variable vector of manifest variables, and residual vector $\mathbf{\Theta}$ is distributed across individuals according to $c \times c$ covariance matrix $\delta_i \in \mathbb{R}^{c \times 1}$.

2.1. Continuous time and SEM

Continuous time models have already been implemented as structural equation models, using either non-linear algebraic constraints (Oud and Jansen 2000) or linear approximations of the matrix exponential (Oud 2002). Our formulation uses either the SEM RAM (reticular action model) specification as per McArdle and McDonald (1984), or the state space form recently added to **OpenMx** (Neale *et al.* 2015; Hunter 2014). For details on the equivalence and differences between SEM and state space modelling techniques, see Chow, Ho, Hamaker, and Dolan (2010). Expectation matrices are generated for each individual according to the specified inputs, constraints, and observed timing data. Optimization using either full information maximum likelihood or the Kalman filter within **OpenMx** is then used to estimate the parameters. For more detailed information on the specification of continuous time structural equation models, the reader is referred to Oud and Jansen (2000); Arnold (1974); Singer (1998); Voelkle *et al.* (2012). Note that while earlier incarnations of continuous time modelling focused on approaches to implement the matrix exponential, **OpenMx** now includes a form of the exponential recommended in computational contexts, the scaling and squaring approach with Pade approximation (Higham 2009), which has been implemented in **ctsem** accordingly.

3. ctsem package overview and installation

3.1. Package overview

Estimating continuous time models via **ctsem** comprises five steps: First, **ctsem** must be correctly configured, which we detail in Section 3.2. Second, the data must be adequately prepared (Section 4). Next, the continuous time model must be specified by creating a **ctsem** model object using the function `ctModel` (Sections 5 and 7). After specification, the model must be fit to the data using the function `ctFit`, after which `summary` and `plot` methods may be used to examine parameter estimates, standard errors, and fit statistics (Section 6). We will discuss these steps in the following.

3.2. Package installation

As **ctsem** is an R package, it requires R to be installed, available from www.r-project.org (R Core Team 2014). The R package **OpenMx** (Neale *et al.* 2015) is required, and is available from <http://openmx.psyc.virginia.edu/>, but will anyway be installed automatically when needed by **ctsem**. To install and load **ctsem** within R:

```
R> install.packages("ctsem", repos = "http://r-forge.r-project.org", type = 'source')
R> library('ctsem')
```

4. Data structure

The internal functions of `ctFit` use data in a wide layout, with all data for each individual in a single row, including the time intervals between measurement occasions for this individual.

4.1. Wide format

[illegible]

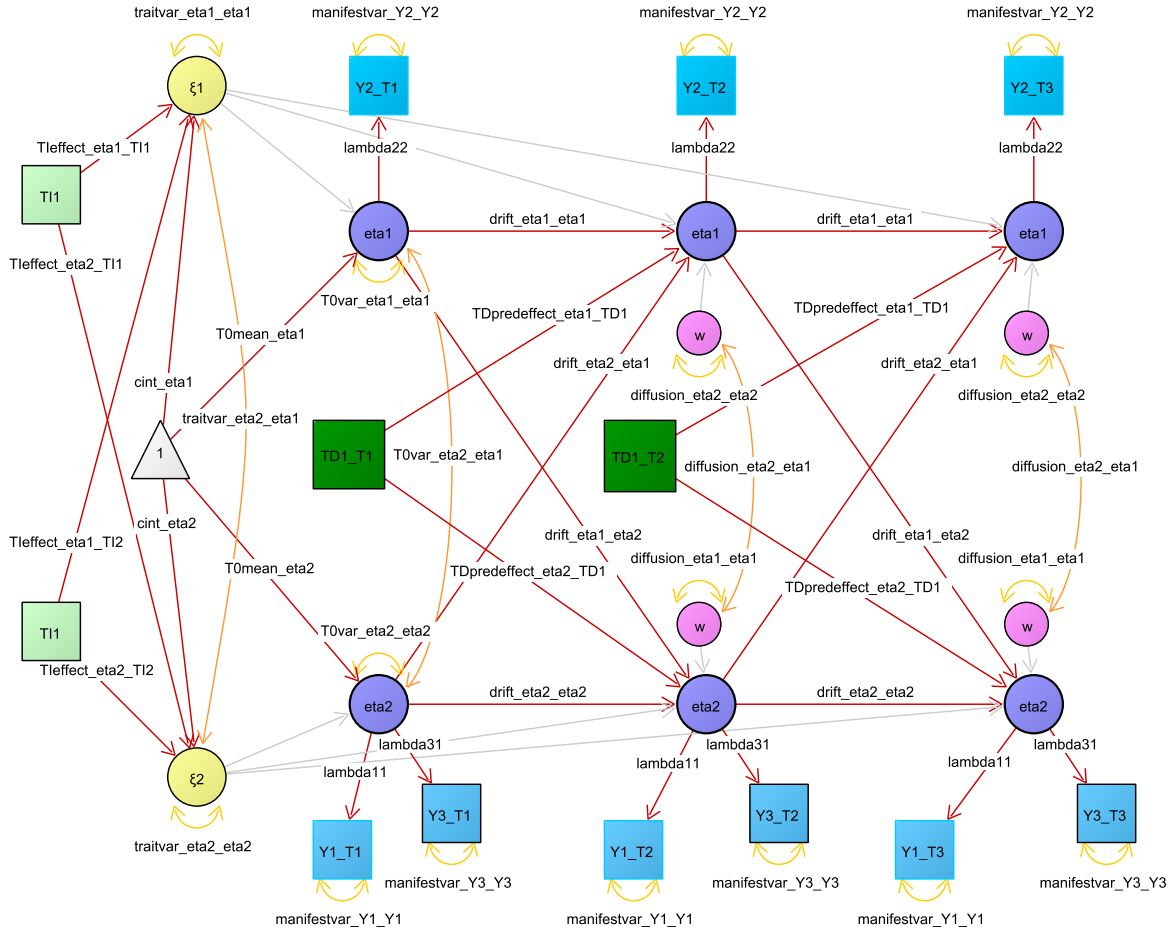

Figure 2: The first three time points of a two process continuous time model, with three manifest indicators (blue) measuring 2 latent processes (purple), one time dependent predictor (dark green), and two time independent predictors (light green). Variance / covariance paths are in orange, regressions in red. Light grey paths indicate those that are constrained to a function of other parameters. Note that the value of parameters for all paths to latents at time 2 and higher do not directly represent the effect, rather, the effect depends on a function of the shown parameter and the time interval Δt . Covariances between the time dependent predictor and traits (yellow) are not drawn.

4.2. Conversion from long format with absolute times

Although **ctsem** uses the wide format as default data input, often data are stored in long format, that is, each subject has multiple rows of data, with each row reflecting a particular measurement occasion. In addition, time intervals may not be readily available at the individual level, instead the *absolute time* when a measurement took place is recorded. To convert from long format, the data must contain a subject identification column, columns for every observed variable, and a time variable. In the example below, three manifest variables of interest (Y1, Y2, Y3) have been observed across a number of occasions, along with one time dependent predictor (TD1) and two time independent predictors (TI1, TI2). The variable 'Time' contains the time when the measurement took place (e.g., in weeks from the beginning of the study).

	subject	Y1	Y2	Y3	TD1	Time	TI1	TI2
[1,]	1	3.13	NA	4.59	0.32625	0	NA	-0.609
[2,]	1	2.30	5.11	2.31	-0.00972	1	-0.607	-0.609
[3,]	1	3.85	4.45	NA	NA	NA	NA	NA
[4,]	1	3.05	3.02	3.11	-0.26912	2	-0.607	-0.609
[5,]	2	5.26	6.06	5.55	0.07493	3	-0.529	-0.233
[6,]	2	5.68	5.64	7.96	-0.63566	4	-0.529	-0.233
[7,]	2	4.68	5.43	4.79	0.26527	5	-0.529	-0.233

Given the specific wide structure required by **ctsem**, and that the time points of measurement may vary across individuals, restructuring from long to wide can be complicated, so we have included functions to manage this. First, the long format data with information on the absolute time of measurement must be converted to the wide format, using the **ctLongToWide** function (The number of Tpoints in the generated data is also messaged to the user at this point, to be used in the next step). Then, subject specific time intervals based on the absolute time information must be generated, using the function **ctIntervalise**. One should take care that the defaults used by **ctIntervalise** for structuring the data and handling missing time information are appropriate.¹

```
R> data('longexample')
R> wideexample <- ctLongToWide(datalong = longexample, id = "subject",
+   time = "Time", manifestNames = c("Y1", "Y2", "Y3"),
+   TDpredNames = "TD1", TIpredNames = c("TI1", "TI2"))
R> wide <- ctIntervalise(datawide = wideexample, Tpoints = 3, n.manifest = 3,
+   n.TDpred = 1, n.TIpred = 2, manifestNames = c("Y1", "Y2", "Y3"),
+   TDpredNames = "TD1", TIpredNames = c("TI1", "TI2") )
```

4.3. Choice of initial time point and time scale

¹By default, when timing information is missing, variables measured at that time are also set to NA for the individual missing the information. Once this is done the actual time of measurement no longer influences parameter estimates or likelihood, so we can set it to an arbitrary minimum interval. By default, the **mininterval** argument to **ctIntervalise** is set to .001. This argument must be set *lower* than the minimum time interval recorded in the data, so that later observations can be adjusted without problems.

Choice of initial time point: Pre-determined or stationary?

An important aspect of continuous time modelling is the choice of how to handle the initial time point. In principle, there are two different ways to do so. One approach is to treat the first time point as *predetermined*, where no assumptions are made about the process prior to the initial time point. In this case, all parameters for the first time point (means, variances, effect of predictors and unit level heterogeneity) are freely estimated. This is the default in **ctsem**, though requires some constraining if fitting a single individual.² When treating the first time point as predetermined, it is important to choose a meaningful starting point, as the process will gradually transition from the variances and means of the initial parameters, towards those of the parameters when the model is stationary. In principle, the initial time point does not have to reflect the first measurement occasion, and can also be set to any time prior. For example it may be meaningful to set T0 to the beginning of the school year, although the first measurement was only taken two weeks after start of school. This can be specified using the **startoffset** argument to **ctIntervalise**, specifying the amount of time prior to the first observed measurement occasion. The other approach is to assume a stationary model, that is, a model where the first observations are merely random instantiations of a long term process with time-invariant mean and variance expectations. Or, put another way, we assume that sufficient time has elapsed from the unobserved, hypothetical start of the process to our first measurement occasion, such that whatever the start values were, they no longer influence the process. Strictly speaking, this requires an infinite length of time, or a process that began in a stationary state. However, in some practical cases without clear trends in the data it is possible that the improvement in estimation due to the stationarity assumption outweighs related losses (this may also be tested). To implement the stationarity assumption the means and variances of the first measurement occasion are constrained according to the model predicted means and variances across all time points. This is specified by including a character vector of the T0 matrices to constrain in the **ctFit** arguments: **stationary = c('T0VAR', 'T0MEANS')** constrains both means and variances to stationarity. The **ctModel** specification of any matrices that are constrained to stationarity is ignored. Note that any between-subject variance parameters, factor loadings, manifest residuals, as well as drift and diffusion parameters, are inherently stationary (given the configuration of **ctsem**). More complex model specification within **ctsem**, or direct modification of the generated **OpenMx** model, is necessary for modelling time variability in the parameters.

Choice of time scale: Individual or sample relative time?

An additional consideration when treating the first time point as predetermined is necessary in cases of individually varying time intervals. Here, two alternatives need to be distinguished. The default option is to treat the observation times as *relative to the individual*, the other is to treat them as *relative to the sample*. When we treat time as relative to the individual, the first observation of every individual is set to measurement occasion T0, even though different individuals may have been recorded many years apart. However if we treat time as relative to the sample, every individual's observation times are set relative to the very first observation in the entire sample. This may result in a larger and sparser data matrix, potentially with only a single observation at the first measurement occasion. To specify sample relative time when converting from absolute time to intervals, set the argument **individualRelativeTime**

²Either T0VAR or T0MEANS must be fixed, see Section 7.3.

= `FALSE` in the `ctIntervalise` function. The choice between the individual or sample relative time may influence parameter estimates when the processes are not stationary. One way of deciding between the two may be to observe whether the changes of the individuals' processes is more closely aligned with the sample relative or individual relative time. The change in processes may be more aligned with individual relative time when we expect that the activity of measurement relates to changes in the process. Consider for instance the relation between abstinence behaviour and mood among individuals attending an alcohol addiction clinic. Different individuals may come and go from the clinic over many years, but the mean level of abstinence is likely related to when each individual began attending the clinic and being measured – not the specific date the observation took place. In contrast, sample relative time could be more appropriate for a study of linguistic abilities in a cohort of schoolchildren over the years, with some individuals observed early and some only observed later, once they are older and more developed. In this case, we may expect changes in the average linguistic ability related to sample time. Another example that becomes conveniently available with continuous time models and these functions is to arrange the data in individual relative fashion but using age as the timing variable. In this case, age-related developmental trajectories may be studied. When considering these options one should be aware that consistent up or down trends over time may confound dynamic parameter estimates, if the innovation (latent residual) at t is correlated with the process at $t - 1$. Pre-processing approaches that remove trend components, such as controlling for age or year, removing a linear trend, or differencing scores, *may* provide some check on model estimates, but the ramifications of these should be carefully considered. Alternatively one may wish to explicitly model the diffusion process, discussed in Section 7.5.

5. Model specification

Continuous time models are specified via the `ctModel` function. This function takes as input a series of arguments and parameter matrices, and outputs a list object containing matrices to be later evaluated by the `ctFit` function. The `ctModel` function contains many defaults that should be generally applicable and safe, in that most parameters are specified to be freely estimated, with a few exceptions.³ However, as with all default settings, they should be checked as they may not be applicable. The arguments to the `ctModel` function and the relation to equations in Section 2 are shown in Table 1 (required specification) and Table 2 (optional specification). The matrices can be specified with either character labels, to indicate free parameter names, or numeric values, which indicate fixed values. A mixture of both in one matrix is fine. These generally need to be set when constraining parameters to equality (same character label), when fixing certain parameters to specific values (for instance, when you do not wish to have a certain parameter in the model, or when testing if an effect is different from 0), or when assigning non-standard names to output parameters. An example model specification relying heavily on the defaults is:

```
R> examplemodel <- ctModel(n.latent = 2, n.manifest = 2, Tpoints = 3,
+   LAMBDA = diag(2))
```

³`ctModel` defaults that *may* not be considered safe, as they are not freely estimated, are the MANIFEST-MEANS, TRAITVAR and MANIFESTTRAITVAR matrices. These were set to ensure that the defaults are appropriate also for single indicator and $N = 1$ cases, and because generally only one of the two trait matrices can be set at once. See Section 7.3 regarding manifest means, and Section 7.1 regarding the trait matrices.

Argument	Sign	Meaning
n.manifest	c	Number of manifest indicators per individual at each measurement occasion.
n.latent	v	Number of latent processes.
Tpoints		Number of time points, or measurement occasions, in the data.
LAMBDA	Λ	$n.manifest \times n.latent$ loading matrix relating latent to manifest variables.

Table 1: Required arguments for `ctModel`.

Argument	Sign	Default	Meaning.
manifestNames		Y1, Y2, etc	n.manifest length character vector of manifest names.
latentNames		eta1, eta2, etc	n.latent length character vector of latent names.
T0VAR		free	symmetric $n.latent \times n.latent$ matrix of latent process initial variance / covariance.
T0MEANS		free	$n.latent \times 1$ matrix of latent process means at first time point, T0.
MANIFESTMEANS	τ	0	$n.manifest \times 1$ matrix of manifest means.
MANIFESTVAR	Θ	free diag	symmetric $n.manifest \times n.manifest$ matrix of variance / covariance between manifests (i.e., measurement error).
DRIFT	A	free	$n.latent \times n.latent$ matrix of continuous auto and cross effects.
CINT	κ	free	$n.latent \times 1$ matrix of continuous intercepts.
DIFFUSION	Q	free	symmetric $n.latent \times n.latent$ matrix of diffusion process variance / covariance.
TRAITVAR	ϕ_{ξ}	NULL	NULL if no trait variance, or lower diagonal $n.latent \times n.latent$ cholesky matrix of trait variance / covariance.
MANIFESTTRAITVAR	ϵ	NULL	NULL if no trait variance on manifest indicators, or $n.manifest \times n.manifest$ lower diagonal variance / covariance cholesky matrix.
n.TDpred	l	0	Number of time dependent predictors in the dataset.
TDpredNames		TD1, TD2, etc	n.TDpred length character vector of time dependent predictor names.
TDPREDMEANS		free	$n.TDpred \times (Tpoints-1)$ rows \times 1 column matrix of time dependent predictor means.
TDPREDEFFECT	M	free	$n.latent \times n.TDpred$ matrix of effects from time dependent predictors to latent processes.
T0TDPREDCOV		free	$n.latent \times ((Tpoints-1) \times n.TDpred)$ covariance matrix between latents at T0 and time dependent predictors.
TDPREDVAR		free	symmetric $(n.TDpred \times (Tpoints-1)) \times (n.TDpred \times (Tpoints-1))$ lower diagonal variance / covariance cholesky matrix for time dependent predictors.
TRAITTDPREDCOV		free	$n.latent$ rows \times $(n.TDpred \times (Tpoints-1))$ columns covariance matrix for latent traits and time dependent predictors.
TDTIPREDCOV		free	$(n.TDpred \times (Tpoints-1))$ rows \times $n.TIpred$ columns covariance matrix between time dependent and independent predictors.
n.TIpred	p	0	Number of time independent predictors.
TIpredNames		TI1, TI2, etc	n.TIpred length character vector of time independent predictor names.
TIPREDMEANS		free	$n.TIpred \times 1$ matrix of time independent predictor means.
TIPREDEFFECT	B	free	$n.latent \times n.TIpred$ effect matrix of time independent predictors on latent processes.
T0TIPREDEFFECT		free	$n.latent \times n.TIpred$ effect matrix of time independent predictors on latents at T0.
TIPREDVAR		free	symmetric $n.TIpred \times n.TIpred$ lower diagonal variance / covariance cholesky matrix for time independent predictors.
startValues		NULL	a named vector, where the names of each value must match a parameter in the specified model, and the value sets the starting value for that parameter during optimization.

Table 2: Optional arguments for `ctModel`.

A visual representation of this model is shown in Figure 3. With `n.latent = 2`, we have specified a model with 2 latent processes, shown in purple. Each of these is measured by a single manifest indicator (in blue), for a total of 2 manifest variables, specified with `n.manifest = 2`. Loadings between latents and manifests are fixed to 1.00 (indicated by the 2x2 diagonal LAMBDA matrix) at 3 measurement occasions, specified by `Tpoints = 3`. Because no other parameters are specified, the model defaults are used, resulting in a bivariate latent process model where each manifest variable has a measurement error variance (`manifestvar_Y1_Y1`, `manifestvar_Y2_Y2`), and a mean fixed to 0. The initial latent variables of each process each have a freely estimated mean (`T0mean_eta1`, `T0mean_eta2`), variance (`T0var_eta1_eta1`, `T0var_eta2_eta2`), and covariance (`T0var_eta2_eta1`). Subsequent latent variables of each process all have an innovation term, with the variance dependent on a function of the diffusion matrix (variances `diffusion_eta1_eta1`, `diffusion_eta2_eta2`, covariance `diffusion_eta2_eta1`), drift matrix, and time interval Δt (Note that although we speak here of variance and covariance parameters for the sake of intuitive understanding, **ctsem** works with cholesky decomposed covariance matrices, discussed in Section 5.1). Each latent variable in our two processes has continuous auto effects on itself according to the `drift_eta1_eta1` and `drift_eta2_eta2` parameters (the diagonals of the drift matrix), and cross effects to the other process according to the `drift_eta1_eta2` and `drift_eta2_eta1` parameters (the off diagonals). This drift matrix combines with time interval Δt to generate the auto and cross regressions shown in the diagram. As usual, the first process listed in the parameter name represents the row of the drift matrix, and the second the column, with the direction of effects flowing from column to row – so the parameter `drift_eta1_eta2` represents the effect of a change in process 2 on later values of process 1. Each process also has a continuous intercept (`cint_eta1`, `cint_eta2`), which, in combination with the drift matrix, sets the level to which each process asymptotes. To develop an understanding of the parameter matrices or simply view a model, printing the model object (e.g. `print(examplemodel)`) is recommended. To track how these matrices are used within the complete SEM specification, one must first estimate the model (discussed in Section 6), and may then view the A, S, F or M matrices typical to a RAM specification McArdle and McDonald (1984) via `example1fit$mxobj$A` (for the A matrix).

5.1. Parameter transformations

Rather than directly operate on covariance matrices, **ctsem** takes as input cholesky decomposed covariance matrices (as these allow for unbounded estimation). The cholesky decomposition is such that variance / covariance matrix $\Sigma = LL^T$, where L is lower-triangular. This means that input variance / covariance matrices for **ctsem** must be lower triangular. The meaning of a 0 in the matrix, or diagonals constrained to equality, is the same for both covariance and cholesky decomposition approaches. Note that internally, **ctsem** optimizes over the natural logarithm of the diagonal of any variance / covariance matrices (and the natural logarithm of the negative diagonal of the DRIFT matrix). While these transformations may be seen in the raw **OpenMx** parameter output section of the output summary, this requires no specific knowledge or action, as the transformations take place internally, and the full DRIFT and variance / covariance matrices are displayed in the summary matrices.

6. Model estimation

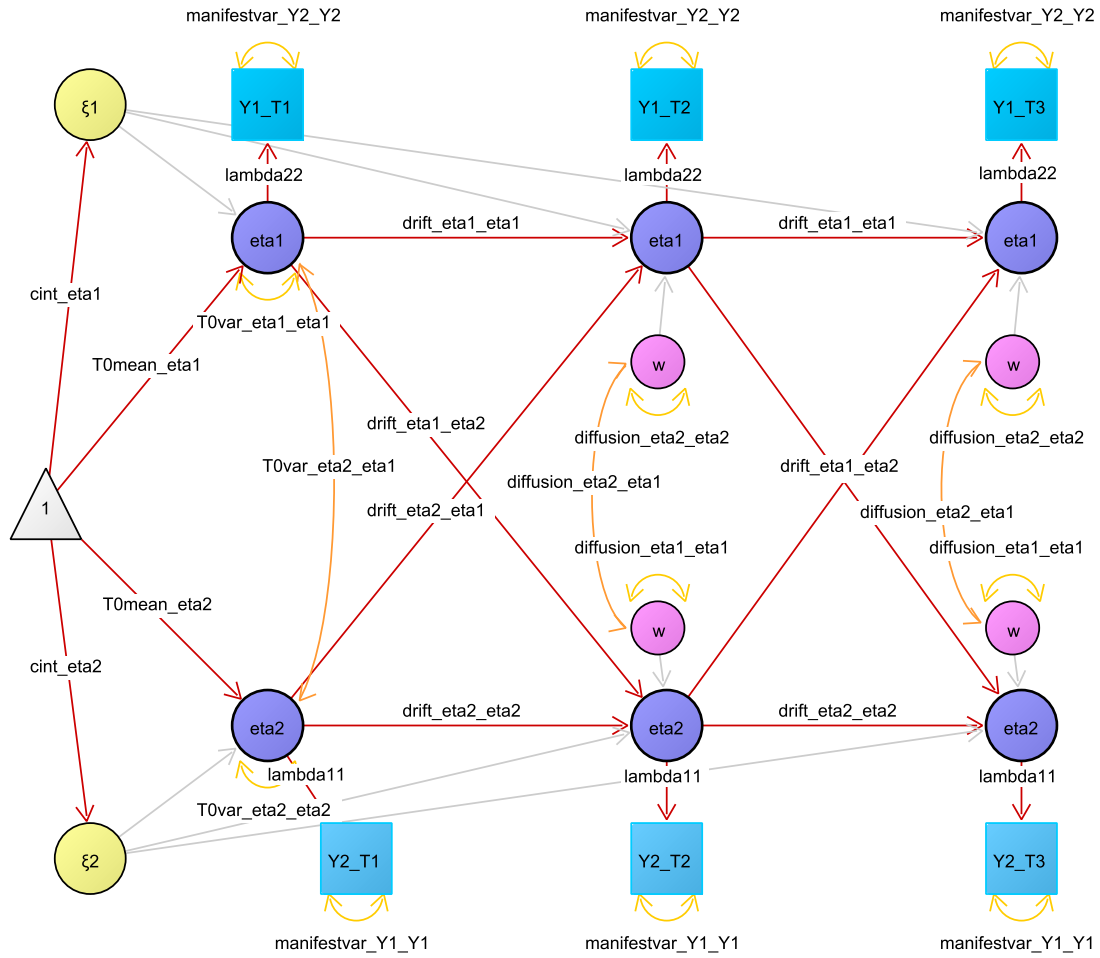

Figure 3: A two process continuous time model with manifest indicators (blue) measuring latent processes (purple). Variance / covariance paths are in orange, regressions in red. Light grey paths indicate those that are either fixed to certain values or constrained to other parameters. Note that the value of the parameters for all paths to latents at time 2 and higher do not directly represent the effect, rather, the effect depends on a function of the shown parameter and the time interval Δt .

The `ctFit` function estimates the specified model, calling the data in wide format along with the `ctsem` model object. For an example, we can fit a similar model to that defined in Section 5. We first load an example dataset contained in the `ctsem` package, then use the `ctFit` function for parameter estimation. Output information can be obtained via the `summary` function. The dataset used in this example, is a simulation of the relation between leisure time and happiness for 100 individuals across 6 measurement occasions. Because our data here does not use the default manifest variable names of `Y1` and `Y2`, but rather `LeisureTime` and `Happiness`, we must include a `manifestNames` character vector in our model specification. Because each manifest directly measures a latent process, we can use the same character vector for the `latentNames` argument, though one could specify any character vector of length 2 here, or rely on the defaults of `eta1` and `eta2`.

```
R> data('ctExample1')
R> example1model <- ctModel(n.latent = 2, n.manifest = 2, Tpoints = 6,
+   manifestNames = c('LeisureTime', 'Happiness'),
+   latentNames = c('LeisureTime', 'Happiness'), LAMBDA = diag(2))
R> example1fit <- ctFit(datawide = ctExample1, ctmodelobj = example1model)
R> summary(example1fit)
```

The output of `summary` after fitting such a model includes a range of matrices representing the continuous time parameters (e.g., DRIFT), discrete time transformations of these parameters for the time interval $\Delta t = 1$ (e.g., discreteDRIFT), and when appropriate, asymptotic values for the parameters as the time interval Δt approaches ∞ (e.g., asymDIFFUSION). When appropriate, standardised matrices are output with the suffix 'std'.⁴ The `$omxsummary` portion of the summary output contains information directly from the `OpenMx` summary function, including the estimated parameters and fit information such as the -2LL, AIC, and BIC. See the `OpenMx` user guide (Boker *et al.* 2014) for further details.

```
R> summary(example1fit)['discreteDRIFTstd']
```

```
$discreteDRIFTstd
      LeisureTime Happiness
LeisureTime    0.9698   -0.0438
Happiness       0.0131    0.8440
```

The output above shows the standardised discrete time equivalent of the DRIFT matrix for time interval $\Delta t = 1$ as reported by `summary`. This is provided for convenience, but one should note that it only represents the temporal effects given the specific interval of 1 unit of time (The specific interval shown for the discrete summary matrices may be modified with the argument `timeInterval`). The unstandardised discreteDRIFT matrix may be calculated from the continuous drift matrix for any desired interval, with the code `expm(summary(example1fit)$DRIFT * desiredinterval)`, see Equation 2. From the diagonals of the matrix we see that changes in the amount of leisure time one has tend to persist longer (indicated by a higher autoregression) than happiness. The cross-regression in row 2 column 1 suggests that as leisure time

⁴Standardisations are based on only the relevant variance, not the total. For instance, DRIFT parameters are standardised using only the within-subject variance, asymDIFFUSION, because DRIFT parameters are typically intended to represent individual, or average individual, temporal dynamics.

increases, this tends to be followed by *increases* in happiness. However, the cross-regression in row 1 column 2 suggests that as happiness increases, this tends to be followed by *reductions* in leisure time. While these results are accurate for the specified model, they do not represent the generating model for this data, which we explain more of in Section 7.1 on unobserved heterogeneity.

6.1. Comparing different models

Suppose we wanted to test the model we fit above against a model where the effect of happiness on later leisure time (parameter `drift_LeisureTime_Happiness`) was constrained to 0. First we specify and fit the model under the null hypothesis by taking our previous model and fixing the desired parameter to 0:

```
R> testmodel <- example1model
R> testmodel$DRIFT[1, 2] <- 0
R> testfit <- ctFit(datawide = ctExample1, ctmodelobj = testmodel)
```

The result may then be compared to the original model with a likelihood ratio test, using the **OpenMx** function `mxCompare`. To use this function a base model fit object and a comparison model fit object must be specified, with the latter being a constrained version of the former. Note that `ctsem` stores the original **OpenMx** fit object under a `$mxobj` sub-object, which must be referenced when using **OpenMx** functions directly.

```
R> mxCompare(example1fit$mxobj, testfit$mxobj)
```

	base	comparison	ep	minus2LL	df	AIC	diffLL	diffdf	p
1	ctsem	<NA>	16	2905	1184	537	NA	NA	NA
2	ctsem	ctsem	15	2920	1185	550	14.8	1	0.000117

According to the conventional $p < .05$ criterion, results show that the more constrained model fits the data significantly worse, that is, happiness has a significant effect on later leisure time for this model and data. An alternative to this approach is to estimate likelihood based 95% confidence intervals for our parameters of interest:

```
R> example1cifit <- ctFit(datawide = ctExample1, ctmodelobj = example1model,
+   confidenceintervals = 'DRIFT')
```

	lbound	estimate	ubound
ctsem.DRIFT[1,1]	-0.0511	-0.0285	-0.00908
ctsem.DRIFT[2,1]	-0.0102	0.0264	0.06316
ctsem.DRIFT[1,2]	-0.1305	-0.0836	-0.04010
ctsem.DRIFT[2,2]	-0.4016	-0.3205	-0.25492

Now the `summary` function reports 95% confidence bounds for the continuous drift parameters, which in case of `drift_LeisureTime_Happiness` does not include 0. For complicated models, the estimation of confidence intervals may increase computation time considerably. Note that although the standard errors of parameter estimates may be automatically returned

via **OpenMx** and displayed via **summary**, likelihood based confidence intervals are the recommended approach because confidence intervals are unlikely to be symmetric around the point estimate for many parameters in a continuous time model.

6.2. Plots

A visual depiction of the relationships between the processes over time can be obtained by using the **plot** function on any fit object created by **ctFit**. This will show the latent processes' mean trajectories, within-subject variance, stable between-subject variance (when applicable), autoregression, and cross regression plots. Autoregression plots show the impact of a 1 unit change in a process on later values of that process, while cross regression plots show the impact of a 1 unit change in one process on later values of other processes. Plots of the discrete time autoregressive and cross regression coefficients for the above fitted model are shown in the top row of Figure 4.

7. Continuous time models: extensions

7.1. Unobserved heterogeneity

When modelling panel data, the continuous intercept parameter κ reflects the expected value for continuous time intercept ξ , which, along with the initial means, determines the average level and mean trajectory of a process. In panel data, however, it is common that *individuals* exhibit stable differences in the level. Within *ctsem* we call such stable differences *traits*, but they may also be thought of more abstractly as *unit level* or *between person* differences, or *unobserved heterogeneity*. When individuals exhibit this trait variance, fitting a model that fails to account for it will result in parameter estimates that will not reflect the processes of individual subjects, but will mix between and within-person information (Balestra and Nerlove 1966; Oud and Jansen 2000; Halaby 2004). To account for this bias, individual differences can be incorporated in two different ways. One way is to control for observed covariates as will be discussed in Section 7.2.1. As covariates are likely to be insufficient, one may also estimate the latent trait variance by estimating the variance and covariance ϕ_ξ of the intercept parameters ξ across individuals.⁵ In *ctsem*, freely estimated latent trait variance may be added with the argument **TRAITVAR** = "auto" to the **ctModel** command. If the user is interested in a specific variance-covariance structure, it is of course also possible to specify the $n.\text{latent} \times n.\text{latent}$ matrix of free or fixed parameters by hand. To illustrate the inclusion of trait variance, we fit the same model on simulated leisure time and happiness introduced above, but also model the trait variance.

```
R> data('ctExample1')
R> traitmodel <- ctModel(n.manifest = 2, n.latent = 2, Tpoints = 6,
```

⁵Note that this is a substantially different approach to achieve unbiased effect estimates than the common *fixed effects* approach (see for example Mundlak 1978), as our SEM specification, while essentially a *random effects* model which have typically been associated with bias for within effects, allows unbiased estimation of *within* and *between* effects at the same time. For further details on the estimation of unobserved heterogeneity in an SEM context, see Bollen and Brand (2010), and in the continuous time case Voelkle, Driver, and Oud (2015).

```

+ LAMBDA = diag(2), manifestNames = c('LeisureTime', 'Happiness'),
+ latentNames = c('LeisureTime', 'Happiness'), TRAITVAR = "auto")
R> traitfit <- ctFit(datawide = ctExample1, ctmodelobj = traitmodel)

```

Figure 4: Top row shows parameter plots without accounting for trait variance, bottom row with trait variance accounted for.

From Figure 4, we can see that after accounting for differences in the base levels of leisure time and happiness, the estimated auto and cross regression effects between latent processes are very different. Auto effects (persistence) have reduced, and the magnitude and sign of the cross effects have switched. Now, rather than a *decrease in leisure time* predicting an *increase in happiness*, after controlling for unobserved heterogeneity we see instead that *increases in leisure time* predict later *increases in happiness*.

Traits at the indicator level

Beyond differences in the level of the latent process, it is also possible that stable individual differences in the level of some or all indicators of a process may exist, and as such may be better accounted for at the measurement level. Take for instance a latent process, happiness, estimated using three survey questions at 10 time points for multiple individuals. The means for question one are fixed to 0 to identify the model, while those for questions two and three are 2.50 and 1.20 respectively. According to the models we have described so far, the estimated (or fixed) manifest means apply equally to all individuals, and deviations from this are taken to represent genuine information about the latent process. However, consider that question three queries happiness with work, which may for some people be consistently high, independent of their actual latent happiness, and for some may be consistently low. Calculating the latent process using the same mean for happiness with work again confounds between and within person information, but we can account for this by using what we will

refer to as *manifest traits* – an additional, time invariant variance-covariance structure on the measurement level. These are specified by including the `MANIFESTTRAITVAR` matrix in the `ctModel` specification, either as `MANIFESTTRAITVAR = "auto"` wherein time invariant variance and covariance for all indicators is freely estimated, or the $n.manifest \times n.manifest$ matrix can be specified explicitly as usual. Such a specification may allow for improved fit of factor models, more realistic estimates of the dynamics of individual processes, and the testing of measurement related hypotheses. Note however that because process level traits are likely to be difficult to identify in a model that also contains manifest level traits, it is important to decide at which level to account for unobserved heterogeneity, or how to constrain and identify the model.

7.2. Predictors

ctsem allows the inclusion of *time independent* as well as time *time dependent* predictors. Time independent predictors could be variables such as gender, personality or socio-demographic background variables that remain constant over time. An example of a time dependent predictor could be a financial crisis, which all individuals in the sample experience at the same time, or the death of a loved one, which only some individuals may experience and for whom the time point of the event may differ. Both events may be thought of as adding some relatively distinct and sudden change to an individual's life, which influences the processes of interest. Time dependent predictors are distinguished from the endogenous latent processes in that they are assumed to be independent of fluctuations in the processes – changes in the latent processes do not lead to changes in the predictor. Furthermore, no temporal structure between different time points is modelled. Because of these two assumptions, in any case where the time dependent predictor depends on earlier values of either itself or the latent process, it may be better to model it as an additional latent process.

Time independent predictors

Time independent predictors are added by including the data as per the structures shown in Section 4, and specifying the number of time independent predictors, `n.TIpred`, in the `ctmodel` arguments. If not using the default variable naming, a `TIpredNames` character vector should also be specified. For an example, we add the 'number of close friends' as a time independent predictor to the earlier leisure time and happiness model. Note that, just like in any conventional regression analysis, if time independent predictors are not centered around 0, the estimate of continuous intercept parameters depends on the mean of the predictor.

```
R> data('ctExample1TIpred')
R> tipredmodel <- ctModel(n.manifest = 2, n.latent = 2, n.TIpred = 1,
+   manifestNames = c('LeisureTime', 'Happiness'),
+   latentNames = c('LeisureTime', 'Happiness'),
+   TIpredNames = 'NumFriends',
+   Tpoints = 6, LAMBDA = diag(2), TRAITVAR = "auto")
R> tipredfit <- ctFit(datawide = ctExample1TIpred, ctmodelobj = tipredmodel)
R>
R> summary(tipredfit)['TIPREDEFFECT']
R> summary(tipredfit)['discreteTIPREDEFFECT']
R> summary(tipredfit)['asymTIPREDEFFECT']
```

```
R> summary(tipredfit)['addedTIPREDVAR']
```

\$TIPREDEFFECT		\$asymTIPREDEFFECT	
	NumFriends		NumFriends
LeisureTime	0.061	LeisureTime	0.156
Happiness	0.132	Happiness	0.316
\$discreteTIPREDEFFECT		\$addedTIPREDVAR	
	NumFriends		LeisureTime Happiness
LeisureTime	0.0503	LeisureTime	0.0263 0.0533
Happiness	0.1076	Happiness	0.0533 0.1078

The matrices output from `summary(tipredfit)` will now include matrices related to time independent predictors, while the estimated parameters now also includes a range of variance, covariance, and effect parameters for time independent predictors. The parameters `TIpred_LeisureTime_NumFriends` and `TIpred_Happiness_NumFriends` reflect the continuous time effects of the number of close friends (TI1) on the processes of leisure time and happiness, however these effects may be more easily understood by referring to the matrix output. Matrix `TIPREDEFFECT` displays the continuous time parameters, however `discreteTIPREDEFFECT` shows the effect added to the processes for each unit of time, which may provide a useful comparison with discrete time models. `asymTIPREDEFFECT` (Asymptotic time independent predictor effect) shows the expected increase in process means given an increase of 1 on the time independent predictor. From these matrices we see that the number of close friends has a positive relationship to both leisure time and happiness. The final matrix, `addedTIPREDVAR`, displays the stable between-subject variance and covariance in the processes accounted for by the time independent predictors.

Time dependent predictors

ctsem allows the specification of time dependent predictors: The fundamental form of such a predictor is that of a sudden impulse to the system which then dissipates back to the process mean, however with some thought it is possible to specify a wide range of effect shapes. Figure 5 provides an example of two different extremes, the basic impulse form and a permanent level change form. A single time dependent predictor can be incorporated in a **ctsem** model by adding the argument `n.TDpred = 1` to the `ctModel` function, as well as a `TDpredNames` vector if not using the default variable naming in your data, then fitting as usual. In the following example, we use the same two simulated processes as above and include an intervention that all individuals experience at time 5. For example, let us assume everyone receives a large amount of money and we are interested in the impact of this monetary gift on leisure time and happiness. We expect that some short term increase in both leisure time and happiness may occur, as people may take holidays or enjoy the unexpected boon otherwise, but we also want to check whether the gift we provide may also cause a longer term adjustment in leisure time or happiness. To this end we first fit a model with the basic impulse effect, coded in the data as a 1 when the intervention occurs and a 0 otherwise.⁶ To aid estimation, because we know

⁶While this form of dummy coding works well, if there are predictors with no variance and the `TDPREDVAR` matrix is not specified, **ctsem** warns the user and fixes `TDPREDVAR` to a diagonal 0.01 matrix.

Figure 5: Two shapes of time dependent predictors: both plots show 5 selected individuals data, all experiencing a time dependent predictor at time point 5. The model-based expected trajectory of the predictor effect (including autoregression) is also shown as a solid black line. On the left, the processes spike up and then dissipate, reflecting a transient change, or *impulse*. On the right, the processes trend upwards towards a new equilibrium, reflecting a stable change in the *level*.

that our intervention was neither related to individuals *initial* (T0) levels, or their *average* levels over time (TRAITVAR), we fix the relevant covariance matrices (T0TDPREDCOV and TRAITTDPREDCOV) to 0.

```
R> data('ctExample2')
R> tdpredmodel <- ctModel(n.manifest = 2, n.latent = 2, n.TDpred = 1,
+   Tpoints = 8, manifestNames = c('LeisureTime', 'Happiness'),
+   TDpredNames = 'MoneyInt', latentNames = c('LeisureTime', 'Happiness'),
+   TOTDPREDCOV = matrix(0, nrow = 2, ncol=7),
+   TRAITTDPREDCOV = matrix(0, nrow = 2, ncol=7),
+   LAMBDA = diag(2), TRAITVAR = "auto")
R> tdpredfit <- ctFit(datawide = ctExample2, ctmodelobj = tdpredmodel)
R>
R> summary(tdpredfit)['TDPREDEFFECT']
R> summary(tdpredfit)['discreteTDPREDEFFECT']
```

\$TDPREDEFFECT		\$discreteTDPREDEFFECT	
	MoneyInt		MoneyInt
LeisureTime	0.633	LeisureTime	0.558
Happiness	0.742	Happiness	0.464

The matrices reported from `summary(tdpredfit)` will now include those related to the time dependent predictor, and the parameters section will include all the additional free parameters estimated, including many variance and covariance related parameters, and the effect

parameters `TDpred_LeisureTime_MoneyInt` and `TDpred_Happiness_MoneyInt`. Looking at the summary matrices, `TDPREDEFFECT` shows us the initial impact, and `discreteTDPREDEFFECT` shows the impact remaining after 1 unit of time. From the matrices, we can see that the monetary intervention relates directly to subsequent increases in leisure time, with also an additional direct effect on happiness. Standardised estimates are not provided because we assume no model for the variance of time dependent predictors. To test the longer term changes introduced via the monetary intervention, we must instead model the impact of the predictor via an additional latent process: We fix the intercepts (`T0MEANS` and `CINT`) and random variance (`T0VAR`, `DIFFUSION`, and `TRAITVAR`) of the additional process to 0; set changes to persist indefinitely via a diagonal `DRIFT` value of 0; fix the impact of the predictor on the new process to 1 (to identify the effect); fix the impact of the two original latent processes on the new to 0 (via the off-diagonals in the third row of `DRIFT`); and estimate the impact of the additional process on our original two processes of interest (via the off-diagonals in the third column of `DRIFT`). Alternatively, one could also estimate the time course of predictor effects by freeing the persistence parameter of the additional process.

```
R> data('ctExample2')
R> tdpredmodel <- ctModel(n.manifest = 2, n.latent = 3, n.TDpred = 1,
+   Tpoints = 8, manifestNames = c('LeisureTime', 'Happiness'),
+   TDpredNames = 'MoneyInt',
+   latentNames = c('LeisureTime', 'Happiness', 'MoneyIntLatent'),
+   TOTDPREDCOV = matrix(0, nrow = 3, ncol = 7),
+   TRAITTDPREDCOV = matrix(0, nrow = 3, ncol = 7),
+   LAMBDA = matrix(c(1,0, 0,1, 0,0), ncol = 3), TRAITVAR = "auto")
R>
R> tdpredmodel$TRAITVAR[3, ] <- 0
R> tdpredmodel$TRAITVAR[, 3] <- 0
R> tdpredmodel$DIFFUSION[, 3] <- 0
R> tdpredmodel$DIFFUSION[3, ] <- 0
R> tdpredmodel$T0VAR[3, ] <- 0
R> tdpredmodel$T0VAR[, 3] <- 0
R> tdpredmodel$CINT[3] <- 0
R> tdpredmodel$T0MEANS[3] <- 0
R> tdpredmodel$TDPREDEFFECT[3, ] <- 1
R> tdpredmodel$DRIFT[3, ] <- 0
R>
R> tdpredfit <- ctFit(datawide = ctExample2, ctmodelobj = tdpredmodel)
R>
R> summary(tdpredfit)['DRIFT']
```

\$DRIFT

	LeisureTime	Happiness	MoneyIntLatent
LeisureTime	-0.2284	-0.0317	0.07430
Happiness	0.0427	-0.4563	-0.04648
MoneyIntLatent	0.0000	0.0000	-0.00001

```
R> summary(tdpredfit, timeInterval = 20)['discreteTDPREDEFFECT']
```

```
$discreteTDPREDEFFECT
                MoneyInt
LeisureTime    0.3376
Happiness      -0.0699
MoneyIntLatent 0.9998
```

Now, if we look at column 3 of the DRIFT matrix, we see that the long term monetary intervention process appears to cause increases in leisure time, but potentially reductions in happiness. The discreteTDPREDEFFECT matrix after 20 time units shows the total expected effect of the predictor (both the impulse and level component) on the processes, and these effects can also be seen in the means when plotting.

7.3. $N = 1$ time series with multiple indicators

In the examples so far, we have dealt with multiple individuals with relatively few measurement occasions, and latent processes have been estimated by a single indicator. However, *ctsem* may also be used for the analysis of time series data for single subjects observed at many measurement occasions, as well as the estimation of latent factors estimated from multiple indicators. With single-subject data, a Kalman filter implementation is typically far quicker than the matrix arrangement we use for multiple subjects, however *ctsem* allows either to be used. To illustrate these features, we perform a dynamic factor analysis on a single individual, with three manifest indicators measured at 50 occasions. Because the model is fitted to a single individual, we cannot freely estimate both the latent variance and mean at the first measurement occasion, but we must fix the 1×1 TOVAR matrix to a reasonable value, or implement stationarity constraints as discussed in Section 4.3. The precise fixed value becomes irrelevant as the time series length increases (Durbin and Koopman 2012). Note that in this example the LAMBDA matrix specifies a loading of 1.00 for manifest Y1, while loadings for Y2 and Y3 are freely estimated. Similarly, the mean for Y1 is fixed to 0, with the others free (by default these would be fixed to 0, but this may be too restrictive for a factor model). These constraints serve to identify the measurement model without further constraining it. Note also that although *ctsem* uses the Kalman filter by default when a single subject is specified, this can be overridden by specifying the `objective = "mxRAM"` argument to `ctFit`, if one wishes to use the slower RAM implementation. The Kalman filter may also be specified for multiple subjects. In this case, between subject trait or time independent predictor matrices are ignored, and instead any free continuous intercept parameters are estimated as different for each individual (Depending on the amount of data, this approach may be more likely to overfit).

```
R> data('ctExample3')
R> model <- ctModel(n.latent = 1, n.manifest = 3, Tpoints = 100,
+   LAMBDA = matrix(c(1, 'lambda2', 'lambda3'), nrow = 3, ncol = 1),
+   MANIFESTMEANS = matrix(c(0, 'manifestmean2', 'manifestmean3'), nrow = 3,
+     ncol = 1))
R> fit <- ctFit(data = ctExample3, ctmodelobj = model, objective = 'Kalman',
+   stationary = c('TOVAR'))
```

7.4. Multiple group continuous time models

In some cases, certain groups or individuals may exhibit different model parameters. We can investigate group or individual level differences by specifying a multiple group model using the `ctMultigroupFit` function. For this example, we will use the same model structure as in the single subject example from Section 7.3, but apply it to two groups of 10 individuals, whom we expect to exhibit differences in the loading of the third manifest variable. When using `ctMultigroupFit`, all parameters are free across groups by default. However, in addition to the standard model specification you may also specify either a *fixed model*, or a *free model*. A fixed model should be of the same structure as the base model, with any parameters you wish to constrain across groups set to the character string 'groupfixed'. The value for any other parameters is not important. Alternatively, one may specify a free model, where any parameters to freely estimate for each group are given the label 'groupfree', and all others will be constrained across groups. In this example, because we only want to examine group differences on one parameter, we specify a free model in which the loading parameter between manifest3 and our latent process eta1 is labelled 'groupfree' – this estimates distinct lambda3 parameters for each group, and constrains all other parameters across the two groups to equality. The group specific parameter estimates will appear in the resulting summary prefixed by the specified *grouping vector*. This is the final requirement for `ctMultigroupFit` and is simply a vector specifying a group label for each row of our data. In this case we have groups one and two, containing the first and the last 10 rows of data respectively, prefixed by the letter 'g' to denote group.

```
R> data('ctExample4')
R>
R> basemodel <- ctModel(n.latent = 1, n.manifest = 3, Tpoints = 20,
+   LAMBDA = matrix(c(1, 'lambda2', 'lambda3'), nrow = 3, ncol = 1),
+   TRAITVAR='auto', MANIFESTMEANS = matrix(c(0, 'manifestmean2',
+     'manifestmean3'), nrow = 3, ncol = 1))
R>
R> freemodel <- basemodel
R> freemodel$LAMBDA[3, 1] <- 'groupfree'
R> groups <- paste0('g', rep(1:2, each = 10), '_')
R>
R> multif <- ctMultigroupFit(datawide = ctExample4, groupings = groups,
+   ctmodelobj = basemodel, freemodel = freemodel)

g1__lambda3 g2__lambda3
      1.417      0.208
```

Looking at the estimated parameters from `summary`, we indeed see a difference between parameters `g1_lambda3` (group 1) and `g2_lambda3` (group 2), and could test this with the usual approaches discussed in Section 6.1. A point to note is that the multiple group and Kalman filter implementations can be easily combined by specifying a distinct group for each row of data. This can allow for an interesting mixture of individual and group level parameters.

7.5. Moving average and oscillations - dynamics on the diffusion process

In the models discussed so far, the latent error term was independent over time. However, what about a situation where we have frequently measured variables which show very slow patterns of change, upwards or downwards trajectories that are maintained over many observations? In exactly the same way as the expected value of the *process* depends on prior values, in such a situation the expected value of the *innovation* would also be predictable based on prior values, rather than always 0. This can provide for oscillations and slower patterns of change, as for example with damped linear oscillators, or moving average effects within the ARMA modelling framework.

Continuous time models of this variety are theoretically plausible, as changes to the level of a process are not necessarily always random in direction, but may depend on contextual circumstances that have some persistence. Consider an individual's overall health over the course of 20 years, sampled every few months. If the individual changes exercise or eating habits, changes in health do not manifest instantly, rather we could expect either a slow increase or slow reduction, depending on whether the change of habits was positive or negative. Thus, for many measurements, the change in health from the previous measurement will likely be in the same direction as the change was one step earlier. The following details how to specify such a model, generate data using the `ctGenerate` function, simply plot the generated data, and estimate the parameters.

```
R> testm <- ctModel(Tpoints = 200, n.latent = 2, n.manifest = 1,
+   LAMBDA = matrix(c(1, 0), nrow = 1, ncol = 2),
+   DIFFUSION = matrix(c(0, 0, 0, 1), 2),
+   MANIFESTVAR = diag(.4,1),
+   DRIFT = matrix(c(0, -.1, 1, -.3), nrow = 2),
+   CINT = matrix(c(1, 0), nrow = 2))
R>
R> data<-ctGenerate(testm,n.subjects=1,burnin=200,dT=1)
R>
R> ctIndplot(data,n.subjects=1,n.manifest=1,Tpoints=200)
R>
R> model <- ctModel(Tpoints = 200, n.latent = 2, n.manifest = 1,
+   LAMBDA = matrix(c(1, 0), nrow = 1, ncol = 2),
+   DIFFUSION = matrix(c(0, 0, 0, 'diffusion'), 2),
+   DRIFT = matrix(c(0, 'regulation', 1, "diffusionAR"), nrow = 2),
+   CINT = matrix(c("processCINT", 0), nrow = 2))
R>
R> fit<-ctFit(data,model,stationary=c('TOMEANS','TOVAR'))
```

In the above, we focus on a model for a single subject, and specify with LAMBDA that a single manifest variable measures only the first latent process. With DIFFUSION we specify that only the 2nd process, our unobserved diffusion process, experiences standard random innovations. With DRIFT, we specify that the 2nd process has a freely estimated autoregression term, that the diffusion process directly impacts the first process with a 1:1 relationship, and that as the level of the main process increases, the level of the diffusion process decreases – providing necessary regulation. With CINT we specify that only the main process has a freely estimated continuous intercept (necessary for identification in this case). [Voelkle and Oud \(2013\)](#) discuss modelling a damped linear oscillator in detail, however here we demon-

strate how to load the data and fit the oscillating model from their paper. In this case, we also specify good starting values with the `startValues` argument to `ctModel`.

```
R> data('Oscillating')
R>
R> inits <- c(-38, -.5, 1, 1, .1, 1, 0, .9)
R> names(inits) <- c('cross','auto', 'diffusion22',
+   'T0var11', 'T0var21', 'T0var22','m1', 'm2')
R>
R> oscillatingm <- ctModel(n.latent = 2, n.manifest = 1, Tpoints = 11,
+   MANIFESTVAR = matrix(c(0), nrow = 1, ncol = 1),
+   LAMBDA = matrix(c(1, 0), nrow = 1, ncol = 2),
+   TOVAR = matrix(c('T0var11', 'T0var21', 0, 'T0var22'), nrow = 2, ncol = 2),
+   DRIFT = matrix(c(0, "crosseffect", 1, "autoeffect"), nrow = 2, ncol = 2),
+   CINT = matrix(0, ncol = 1, nrow = 2),
+   DIFFUSION = matrix(c(0, 0, 0, "diffusion"), nrow = 2, ncol = 2),
+   startValues = inits)
R>
R> oscillatingf <- ctFit(Oscillating, oscillatingm)
```

8. Additional specification options and tips for model estimation

Given the complexity of parameter constraints, model estimation is sometimes more difficult than for standard structural equation models. To ensure reliable estimation, there are some additional approaches that may be helpful. The simplest approach is to try fitting using the argument `carefulFit = TRUE` for the `ctFit` function. This initiates a two-step procedure, in which the first step penalises the likelihood⁷ to help maintain potentially problematic parameters close to 0, and then uses these estimates as starting values for maximum likelihood estimation. Beyond this, as a general guideline we suggest starting with simpler, more constrained models and freeing parameters in a stepwise fashion. This could involve developing the measurement model separately, estimating only autoregressive parameters of the DRIFT matrix at first (in simple models, this means constraining the off-diagonals of the DRIFT matrix to 0), or fixing the factor loading matrix prior to free estimation. If progression to additional complexity results in worse likelihood values, the optimization has resulted in a local rather than global optimum. In such a case, ensure that sensible starting values are specified. These may be specified in the `startValues` argument of `ctModel`, as shown in the oscillating example of Section `sec:diffusiondynamics`, or alternatively, the raw **OpenMx** parameters may be extracted from a previous fit using the **OpenMx** function `omxGetParameters`, and used with `ctFit` via the `omxStartValues` argument. The following code is an example of how this would be applied to the first fitting example, from Section 6.

```
R> omxInits <- omxGetParameters(example1fit$mxobj)
R>
```

⁷The sum of squares of each parameter that is neither a loading nor mean related is multiplied by 1 thousandth of the likelihood, then added to the likelihood

```
R> fitWithInits <- ctFit(data = ctExample1, ctmodelobj = example1model,
+   omxStartValues = omxInits)
```

If stepwise model building with starting values based on simpler fits still fails to produce an improved solution, some of the following suggestions may be helpful. The time scale, although theoretically unimportant in the sense that all time ranges can be accounted for, can be computationally very relevant. It is helpful to choose a scale that roughly matches the expected dynamics – for instance a time scale of nanoseconds for panel data measured yearly would be problematic, instead, a yearly or monthly time scale could be used. Centering the *grand* mean of the variables to 0 can be useful, as can standardising the variances, particularly in cases where both a measurement model and dynamic model are estimated. Trying a different optimizer may help, by default the SLSQP optimizer is requested via **OpenMx**, but setting the argument `optimizer='NPSOL'` to `ctFit` may in some cases be better. Note that for NPSOL, **OpenMx** must be downloaded directly via the **OpenMx** website, rather than via CRAN. One way to search for an improved solution is simply to try many times with varying starting values. This is automated by default using the `mxTryHard` function from **OpenMx**, however you may want to increase the `retryattempts` argument to `ctFit`, or simply re-run `ctFit` many times, as it generates unspecified starting values with some randomness. However, since both automated procedures begin within a similar range, for truly problematic cases one may consider adding more extensive randomness to the starting values manually. In situations with a limited number of time points, you may implement the stationarity assumption, so that parameters related to the first time point are no longer estimated, but constrained to the asymptotic effects, when the time interval $\Delta t \rightarrow \infty$. This can make optimization more straightforward, and may serve as a useful basis for determining starting values, or as a viable model in itself. For more discussion regarding stationarity conditions see Section 4.3. When time intervals vary for every individual, optimization can be quite slow. To quickly estimate approximate versions of a model, you may use the `meanIntervals = TRUE` argument to `ctFit`, which will set every individual's time intervals to the mean of the interval across all individuals. A step further even is to specify the argument `objective = 'cov'` in order to estimate a covariance matrix from the supplied data and fit directly to that. In cases with variability in time intervals these approaches will substantially speed up optimization, but also waste information and bias parameters. Using such an approach in combination with a constrained DRIFT matrix to generate starting values can be an excellent way to increase both speed and reliability of estimation for large or complex problems.

9. Limitations and future directions

Currently, a number of assumptions are present in the specification of continuous time models implemented in **ctsem**. Although the processes are allowed to begin at different levels and variances, from then on a time-invariant model is assumed. Thus, **ctsem** cannot presently account for time-varying aspects of the processes, except in the form of observed exogenous inputs via time dependent predictors. Although as with many discrete models we could free various parameters across measurement occasions, their meaning would become unclear, as each measurement occasion (set of `n.manifest` columns in the wide format data) may contain observations from many different times. Instead, models which allow parameters to vary as a function of time could be incorporated in the future as per the time-varying specification in

Oud and Jansen (2000). As we fit using full information maximum likelihood, standard assumptions regarding multivariate normality apply to any manifest variables. Generalisations of the measurement model to allow for non-normal indicators could be easily implemented using the regular **OpenMx** functionality however. Although we allow for heterogeneity in the level of the processes across individuals, heterogeneity in other parameters is not accounted for, and can only be examined crudely via multiple group approaches. Presently, effects are assumed to be transmitted near instantaneously, as we do not estimate a dead time between inputs and the effect of inputs. Thus, when there is a dead time between an input and its' effect, the model is misspecified. We believe this is unlikely to severely impact estimates unless the dead time is of a similar or greater order of magnitude as observation intervals, however such a parameter can be estimated and incorporated within the continuous time equations (Richard 2003). Although in such areas **ctsem** may benefit from expansion, **ctsem** as it stands allows for the straightforward specification of continuous time dynamic models for both panel and time series data, which may include a measurement model, exogenous predictors, multiple processes, unobserved heterogeneity, multiple groups, as well as easy to specify parameter constraints and more complex dynamic specifications.

10. Acknowledgements

We would like to thank the Intra Person Dynamics and the Formal Methods research groups at the Max Planck Institute for Human Development for assistance with this work, as well as Joshua Pritikin and the **OpenMx** development team for feedback and fast response to issues.
